With careful planning and some fine-tuning, you can get the results you want in ways that are both accurate and fast. If you find that you are not getting the results you want, or if you need to exceed the processing rate of that program, you can "step up" to hardware acceleration. If you want to see how a method works, or you want to estimate the cost of running a method, the profiler can be used in debugging and performance optimization. Profiler A: The only method I know to calculate walltime in a loop is by using PerfMon (Performance Monitor). Just run it on a new process for each calculation and you can get the wall time. For actual values, you need to write your own timer code which can trigger a loop, how to create an event, use a queue to store the start time and check the difference between the time and the event time in order to find the wall time. If you are really determined, you can write a kernel-mode driver and use ReadProcessMemory to monitor the kernel time events. The risk here is that if you will hit a timeout for the user mode interrupt, the monitoring of the kernel mode will stop too. A hard limit can be set with an input device. When you have the walltime, you have to divide by the number of iterations, in order to give the processor time and not the time of the calculation.
